## **Highlights**

- The COVID-19 pandemic has demonstrated a wave pattern similar to previous pandemics
- Treatment guidelines have changed rapidly based on clinical studies
- In our hospital, the use of steroids and noninvasive ventilation increased with time
- During the second wave, patients had a slower progression to death

Clinical characteristics and outcomes of the first two waves of the COVID-19 pandemic in a community hospital: A retrospective cohort study

#### **Abstract**

**Objective:** To describe the clinical characteristics and outcomes of two waves of the COVID-19 pandemic.

**Methods:** We retrospectively reviewed a de-identified dataset of patients with COVID-19 admitted to our community hospital in Evanston, Illinois, from March 1, 2020, to February 28, 2021. We then identified patients from the first wave as those admitted during the initial peak of admissions observed at our hospital between March 1, 2020, and September 3, 2020. The second wave was defined as those admitted during the second peak of admissions observed between October 1, 2020, and February 28, 2021.

**Results:** A total of 671 patients were included. Of those, 399 (59.46%) were identified as patients from the first wave, and 272 (40.54%) were identified as patients from the second wave. Significantly more patients received steroids (86.4% vs. 47.9%, p <.001), remdesivir (59.6% vs. 9.5%, p <.001), humidified high-flow nasal cannula (18% vs. 6.5%, p <.001) and noninvasive ventilation (11.8% vs. 3.3%, p <.001) during the second wave. Patients from the first wave had a greater hazard for death compared to patients from the second wave (Hazard Ratio [HR] 1.62, 95% CI 1.08 – 2.43; p =.019).

**Conclusion:** Among patients hospitalized with COVID-19 in our community hospital, we observed a decrease in case-fatality rate in the second surge of the COVID-19 pandemic compared with the first wave.

## Introduction

From its discovery in December 2019, SARS-CoV-2 has caused global public health emergencies and economic crises. On January 20, 2020, the CDC confirmed the first US laboratory-confirmed case of COVID-19 in the US from samples taken on January 18 in Washington state (Centers for Disease Control and Prevention, 2021). On March 11, 2020, The World Health Organization declared the coronavirus disease 2019 (COVID-19) a pandemic. Many countries around the world, including the USA, experienced a pattern of the pandemic where a first wave occurred during the spring of 2020, that substantially subsided during the summer, and a second wave emerged during the fall of 2020. The intervention approach has changed as the pandemic evolved. In the very beginning, the COVID-19 therapy focused on hydroxychloroquine and azithromycin; however, later, they were shown to be ineffective, and dexamethasone came into play after the preliminary results of the RECOVERY trial (RECOVERY Collaborative Group et al., 2020). Subsequently, among the other candidate therapies, remdesivir has demonstrated efficacy in shortening the time to recovery in adults hospitalized with COVID-19 and had evidence of lower respiratory tract infection (Beigel et al., 2020). Most of the current studies revealed a decrease in mortality from COVID-19 over time (Boudourakis et al., 2021). In this study, we compared characteristics of and case-fatality rate in patients hospitalized with COVID-19 between two waves of the pandemic in a community hospital setting.

#### **Methods**

We retrospectively reviewed a de-identified dataset of 671 patients (399 in the first wave and 272 in the second) with COVID-19 admitted to a community hospital in Evanston, Illinois, from March 1, 2020, to February 28, 2021. The cutoff for the start of the second wave was October 1, 2020, as we noted an acute increase in hospitalizations at our institution after that date again. The cutoff for the end of the second wave was February 28, 2021, after we observed a constant decrease in the number of new hospitalizations (Figure 1). Only first-time hospitalized patients with a laboratory-confirmed COVID-19 infection were included in this study. This study did not include patients with a positive COVID-19 test who did not require hospitalization or patients

without laboratory confirmation of the infection. Infection was confirmed by reverse transcriptase (RT) polymerase chain reaction (PCR) (Abbott™ RealTime™ SARS-CoV-2 assay) or isothermal nucleic acid amplification test (Abbott™ ID NOW COVID-19™ assay) using swab samples from the upper respiratory tract.

Data was collected manually from Electronic Medical Records (Epic Systems software, Verona, WI). Missing values were not imputed and thus were not included in the survival model. For each patient, we collected the following data: age, gender, ethnicity, dwelling, body mass index, comorbidities, smoking status, symptoms, and vital signs on presentation to the hospital, time from symptom onset to presentation to the emergency room, time from symptom onset to admission to the intensive care unit (ICU) if applicable, blood cell count, comprehensive metabolic panel, ferritin, lactate dehydrogenase, D-dimer, IL-6, creatine kinase, procalcitonin, C-reactive protein, lactate, high sensitivity troponin, BNP, triglyceride levels, microbiology data (blood, urine, and sputum culture results), chest x-ray upon presentation, disposition of the patient on the days 1, 3, 5 and 10 of hospitalization and final disposition, highest oxygen support on the floors and ICU, and lowest PaO2/FiO2 ratio.

Moreover, for each patient, we collected the data about different treatment modalities: prone positioning, neuromuscular blockers, vasopressor support, new-onset hemodialysis, and the use of hydroxychloroquine, azithromycin, remdesivir, tocilizumab, steroids, colchicine, atorvastatin, or antibiotics. We also included the hospitalization length of stay, do-not-resuscitate/do-not-intubate (DNR/DNI) status, extubation status, and the main outcome. The five possible outcomes were: discharge home, transfer to a long-term care facility, transfer to a higher level care hospital for extracorporeal membrane oxygenation (ECMO), hospice, or death. Furthermore, for the survival analysis, patients discharged to home or transferred to long-term care facilities or higher level of care were classified as survivors, whereas patients referred to hospice or that died were classified as nonsurvivors (outcome event).

Descriptive statistics were used to summarize the data; categorical variables were described as frequency rates and percentages, and continuous variables were described using median and interquartile range (IQR) values. We used the Mann-Whitney U test, c2 test, or Fisher exact test to compare differences between patients of the first and second wave when appropriate. We used Kaplan-Meier survival curves to characterize differences in survival between the two waves of the pandemic. Patients were followed only during the hospital stay, from presentation to the emergency department (baseline) to the outcome event, and survivors were rightcensored at the time of discharge or transfer out of our institution. We performed a Cox regression model to estimate the hazard ratios [HR] for death and the corresponding 95% confidence intervals (CIs). To minimize confounders, age, dwelling, quick sequential organ failure assessment (qSOFA score), noninvasive ventilation (NIV), and steroids were forced as covariables into the model. Instead of using variable selection algorithms, we opted to fit these variables into the model based on background knowledge from observed clinical characteristics of this population of patients and previously reported cohorts (Heinze et al., 2017). A two-sided alfa of less than .05 was considered statistically significant. Schoenfeld residuals were used to confirm the proportional hazards assumption. The proportionality assumption for each variable was tested for a non-zero slope in a generalized linear regression of the scaled Schoenfeld residuals on functions of time. The P-values used for the non-proportionality test were the Pvalues obtained from the generalized linear regression model (a P-value <0.05 indicated a violation of the proportionality assumption).

#### Results

Patient demographics, characteristics, and comorbidities are described below in **Table 1**. Among 399 patients from the first wave, the median age was 69 years (IQR, 59 – 80 years), 227 (56.9%) were male, 163 (40.9%) were White. Among 272 patients from the second wave, the median age was 69.5 years (IQR, 58 – 80 years), 160 (58.8%) were male, 104 (38.2%) were White. Patient demographics were quite similar between the two waves of evaluated variables except for the percentage of the patients from long-term care facilities. In the first wave, 245

(61.4%) were admitted from a long-term care facility, whereas only 52 (19.1%) in the second wave (Table 1).

Symptoms and vital signs are summarized in **Table 2**. We have seen fewer patients with fever during the second wave, but more patients presented with chills, fatigue, malaise, and gastrointestinal symptoms. Significantly fewer patients had altered mental status (AMS) on presentation (p <.001), which correlates with the decrease in the number of patients admitted from LTCF who are older, more debilitated, and tend to present with atypical symptoms such as AMS (**Table 2**). Laboratory results of patients in two waves of the pandemic and the chest x-ray findings are summarized in **Table 3**. During the second pandemic wave, more patients presented to the hospital with diffuse opacities and less with unilateral opacities.

The interventions performed are presented in Table 4. The use of hydroxychloroquine and colchicine was practically abandoned during the second wave, following updates in the NIH COVID-19 treatment guidelines (National Institutes of Health, 2021). Significantly more patients received steroids (86.4% vs. 47.9%) and remdesivir (59.6% vs. 9.5%) during the second wave. The use of antibacterial therapy decreased from the first to the second wave (90.2% vs. 79.8%). Statistically significant changes were seen in the utilization of the different types of respiratory support in our institution: more NIV was utilized in the second wave (4% vs. 1.3%, p <.024 in the ED and 11.8% vs. 3.3%, p <.001 in ICU or medical floor); additionally, more patients in the second wave received humidified high-flow nasal cannula (15.4% vs. 5.3%, p <.001 on the medical floor or ICU and 18% vs. 6.5%, p <.001 in total) and NIV (9.6% vs. 2.3%, p <.001 on the medical floor or ICU and 11.8% vs. 3.3%, p <.001 in total). Unexpectedly, there was no statistically significant decrease in the rate of invasive mechanical ventilation started in the ICU or in total (11.3% vs. 9.9%, p= .565 and 18.8% vs. 13.2%, p= .057, respectively), though it was seen on presentation to the ED (3.3% vs. 7.5%, p= .022). Despite prone positioning being an effective therapy for ARDS, fewer patients required prone positioning during the second wave (7.7% vs. 15.3%, p= .003). The utilization of vasopressors significantly decreased compared to the first wave (8.5% vs. 17%, p= .001), which correlates with the reduction of septic shock rate.

The outcomes are displayed in Table 4. In our institution, COVID-19 was significantly more accompanied by septic shock during the first wave than the second one (20.8% vs. 12.1%, p=.004). Moreover, the co-infection rate had decreased during the second wave (18% vs. 10%, p=.004). Critical care utilization has significantly decreased in the second wave compared with the first one (33.1% vs. 21.3%, p <.001). However, there was no statistically significant decrease in extubation rate (32% vs. 16.7%, p= .089) or discharge from ICU (49.2% vs. 46.6%, p= .733). There was a large and statistically significant reduction in the case-fatality rate in the second wave (33.3% vs. 18.4%; p <.001). During the first wave, 111 (27.8%) hospitalized patients died, while 39 (14.3%) died during the second wave. Patients from the first wave had a 62% chance of faster progression to death (when chance of faster progression to death = HR/(1 + HR)) (Spruance et al., 2004) compared to patients from the second wave (HR 1.62, 95% CI 1.08 – 2.43; p =.019) (Figure 2). We conducted two sensitivity analyses, given the remarkable difference in patients admitted from LTMF between the first and second pandemic wave. First, we conducted the Cox regression model using dwelling as a stratification variable, allowing separate baseline hazard functions to be fitted within different strata, pooling estimates over strata for an overall comparison of factor levels. In this model, the hazard for inpatient death was still significantly higher among patients admitted during the first wave compared to patients from the second wave (HR 1.5, 95% 1.001 – 2.25; p =.049). Lastly, we conducted a hierarchical Cox regression model evaluating the interaction effects between dwelling and pandemic wave, including the interaction variable in block 2 of the model and testing for fitness. In this model, neither pandemic wave nor the interaction between pandemic wave and dwelling showed a significant increase in the hazard for inpatient death (HR 1.61, 95% CI 0.93 – 2.77, and HR 1.01, 95% CI 0.47 - 2.14, respectively). However, the Omnibus test did not show a significant improvement in model fitness compared to the previous model (Chi-square .001, p = .971).

#### **Discussion**

In this study we describe the clinical characteristics and outcomes of patients hospitalized with COVID-19 during the two first waves of the pandemic. The most striking differences that we

could identify were increased steroid and remdesivir use, more frequent application of NIV, reduced ICU utilization rate, and COVID-19 case-fatality in the second pandemic surge as opposed to the first one. More liberal steroid use in the second wave was primarily linked to the results of the RECOVERY trial, which demonstrated that dexamethasone lowered 28-day mortality among those receiving either invasive mechanical ventilation or other less invasive types of oxygen support (RECOVERY Collaborative Group et al., 2021) Though remdesivir was not efficacious in reducing mortality from COVID-19, its use was superior to placebo in shortening the time of recovery in hospitalized patients (Beigel et al., 2020) We attributed the reduction in ICU utilization rate to the more liberal use of NIV on the medical floors.

The results obtained in our study are consistent with several prior studies. For instance, a single-center study conducted in a tertiary-care hospital in Belgium demonstrated that 30-day mortality between the first and second wave of the pandemic was 74/341 (22%) vs. 98/662 (15%) (p =.007). Significantly more people received corticosteroids in the second wave compared to the first: 404/662 (61%) and 11/341 (3.2%), respectively (p <.001). In the second received high-flow wave. people nasal oxygen (79/662 (12%), p < .0001); p < .0001). remdesivir (88/662 (13.3%),second received ln the wave, no one hydroxychloroquine (0/662 (0%) vs. 249/341 (73%) in the first wave, p <.0001); and significantly fewer patients were transferred to ICU (87/341 (26%), p = .024). Amongst the patients admitted to the ICU, fewer patients required vasopressor support. However, as opposed to our study, there was a statistically significant reduction in the rate of mechanical ventilation and renal replacement therapy among the patients admitted to the ICU (Lambermont et al., 2021).

Another study conducted in Reus, Spain, revealed that the patients in the second wave were younger, and the duration of hospitalization and case-fatality rates were lower than those in the first wave. In the second wave, there were more children, pregnant and post-partum women (Iftimie et al., 2021). A study conducted at Stanford University examined all countries with at least 4000 COVID-19 deaths and demonstrated that the distribution of deaths has been quite similar in both waves, but the number of COVID-19 deaths in nursing home residents has decreased in the second wave, except in Australia (Ioannidis et al., 2021). We have not

explicitly studied mortality rates in different patient populations, but the demographic portion of our results has revealed a significant decrease in the hospitalization rate of patients from LTCF. Most likely, this pattern observed is related to the fact that the first wave of the pandemic may have killed some of the most fragile residents (Chicago Tribune, 2020), which led to improved hygiene measures, infection control, regular testing of the residents and personnel (Illinois Department of Public Health, 2020). We believe that these measures along with the early role out of COVID-19 vaccines among vulnerable population, including LTCF residents, significantly helped transform the demographics of the second wave of the pandemic (City of Evanston, 2020). By August 2021, local LTCFs showed higher rates of vaccinated residents and employees than the overall rates in Illinois, with some facilities reaching up to 93% of vaccinated residents and 78% of employees (Evanston Now, 2021).

Another interesting aspect of the pandemic is the difference in death rates between ethnic groups. A study from England showed that, in the first wave, all ethnic minority groups had a higher risk of COVID-19 related death than the White British population. In the second wave, the reduction in the difference in COVID-19 mortality between people from Black ethnic backgrounds and people from the White British group has been seen; however, the rate of mortality continued to be higher in people from Bangladeshi and Pakistani backgrounds (Nafilyan et al., 2021). In our cohort of hospitalized patients with COVID-19, the White population was more prevalent during the two initial pandemic waves, with slightly more Black or African Americans hospitalized during the first wave than the second wave. With regards to the inpatient case-fatality rate, only the White population and some other ethnicities (other responses not included in the ethnicity categories) showed a significant decrease in the inpatient case-fatality rate during the second wave as compared to the first wave (17.3% vs. 42.9%, p <.001 and 8% vs. 25.7%, p =.039, respectively).

This study is not without limitations. Our hospital population can significantly differ from the populations seen at other locations, and, thus, the results of this study may not be generalizable. We also acknowledge that time cutoffs for defining pandemic surges may slightly

differ between our study and others. Nevertheless, we firmly believe that the results obtained in this study are relevant since it mirrors the trends of the similar medical centers in the USA. Regarding follow-up, given the retrospective nature of this study, we consider the loss-to-follow-up to be minimal. However, we recognize that studying the patients only during their index hospitalization due to COVID-19 and not exploring follow-up after discharge may have introduced bias in the survival analysis. Some patients may have been readmitted and died due to COVID-19 complications. Additionally, the decision to include both deceased patients and patients transferred to hospice into the composite outcome of nonsurvivors could have introduced bias in the survival analysis. However, neither the rates of patients transferred to hospice was not significantly different between the two waves of the pandemic (5.5% vs. 4%, p = .376) nor was the time-to-event among patients transferred to hospice in the two waves (6.5 days [IQR, 5 – 12.25 day] vs. 10 days [IQR, 4 – 14 days] p=.902) and between deceased patients compared to patients transferred to hospice (7 days [IQR, 4 – 13.25 days] vs. 7 days [IQR, 5 – 12.5 days], p = .942).

In conclusion, among 671 patients hospitalized with COVID-19, we observed a decrease in case-fatality rate in the second surge of the COVID-19 pandemic compared with the first wave. It is unclear which factors exactly gave rise to the observed mortality patterns. A better understanding of the disease pathogenesis, improved infection control measures, more tailored and specific treatment regimens, and mutations resulting in changes in the virus biology (such as pathogenicity, infectivity, transmissibility, or antigenicity) could be the contributing factors. The formation and evolution of a pandemic are essential topics that need further study to make better predictions regarding the infection course.

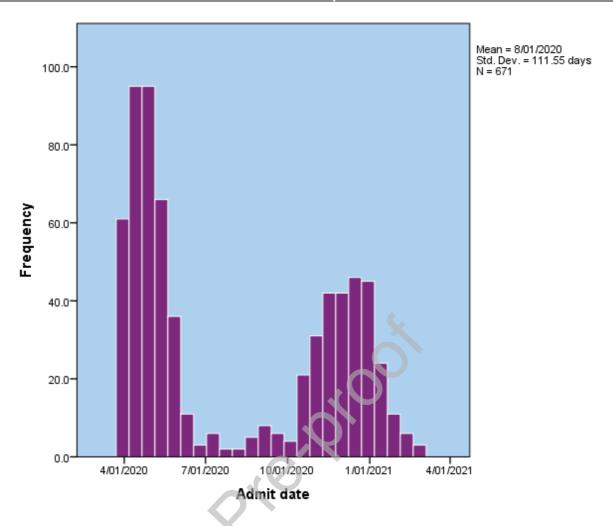

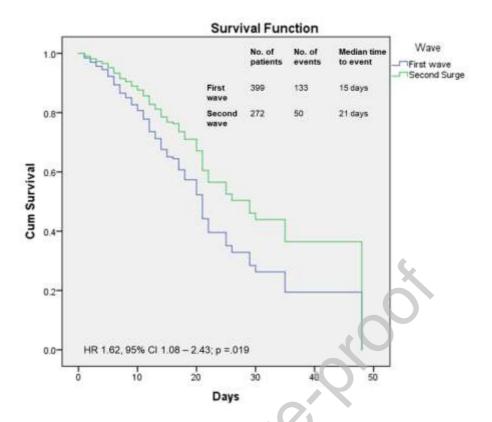

Figure 1. COVID-19 hospitalizations trend from March 1, 2020, to February 28, 2021.

Figure 2. Survival analysis of time to even in patients from the first and second wave of the COVID-19 pandemic in our community hospital.

The hazard ratio with the corresponding 95% confidence intervals were obtained from a multivariable Cox regression model. P-values obtained from the generalized linear regression model of Schoenfeld residuals as a function of time: Pandemic wave, p = .390; Age, p = .928; qSOFA score, p = .063; Bilevel positive airway pressure (BiPAP), p = .994; Humidified high-flow nasal cannula, p = .604; Steroids, p = .249. A P-value <0.05 indicated a violation of the proportionality assumption.

Notes: First wave: March 2020 – September 2020, second wave: October 2020 – January 2021; immunosuppression: any patient on immunosuppressive medications, including steroids (prednisone >20 mg daily or equivalent dose) and biological therapy, patients on chemo- and radiotherapy, HIV positive patients; some other ethnicity includes all other responses not included in the "White", "Latinx", "Black or African American", "Asian", and "Arabic" ethnicity categories as described above. COPD – chronic obstructive pulmonary disease, ESRD – end-stage renal disease, HD – hemodialysis, LTCF – long-term care facility, VTE/PE – venous thromboembolism/pulmonary embolism.

Categorical variables are presented as number (%). Continuous variables are presented as median (interquartile range). *P* values indicate differences between patients of the first and second wave. *P*< .05 was considered statistically significant.

Table 2. Sings, symptoms, and vital signs on presentation

	All	First wave	Second wave

Bilateral opacities	202 (50.6%)	155 (57%)	.103
Diffuse opacities	45 (11.3%)	49 (18%)	.014

Notes: the laboratory results above were obtained within 48 hours of patient presentation to the hospital; ALP – alkaline phosphatase, ALT – alanine aminotransferase, AST – aspartate aminotransferase, BILT – total bilirubin, BNP – brain natriuretic peptide, BUN – blood urea nitrogen, HGB – hemoglobin, IL-6 – interleukin 6, LD – lactate dehydrogenase, PLT – platelet count, TAG – triacylglycerides, WBC – white blood cell count.

Categorical variables are presented as number (%). Continuous variables are presented as median (interquartile range). *P* values indicate differences between patients of the first and second wave. *P*< .05 was considered statistically significant. Variables with missing values are presented with their respective sample size (n).

Notes: ARDS – acute respiratory distress syndrome, DNI – Do Not Intubate, DNR – Do Not Resuscitate, ED – emergency department, HFNC – High-Flow Nasal Oxygen, ICU – intensive care unit, IMV – invasive mechanical ventilation, NIH – National Institutes of Health, NIV – non-invasive ventilation, qSOFA – quick sequential organ failure assessment.

Categorical variables are presented as number (%). Continuous variables are presented as median (interquartile range). *P* values indicate differences between patients of the first and second wave. *P*<.05 was considered statistically significant.
